

ASSESSMENT OF CASSAVA DIVERSITY IN UGANDA USING SSR MARKERS

E.B.Kizito^{1,2}, W.Castelblanco⁴, J. Omara³, A.Bua³, T.G. Egwang², M. Fregene³, U. Gullberg¹

Abstract:

The genetic diversity and differentiation of 272 cassava landrace accessions collected in Uganda is assessed in this study. In addition to this, 20 Tanzanian material was included from a previous study of diversity in Tanzania, 20 material from the Ghanaian germplasm bank, 20 material from Guatemala and 18 from holdings at CIAT and IITA to represent the core collection from Latin America. All together 9 groups or samples, based on country of origin, were created to study genetic diversity and differentiation within each country and among countries. Using simple sequence repeat (SSR) markers, variation in allele frequency at many unlinked loci was used to estimate the parameters of genetic diversity and differentiation, and to estimate the strengths of various forces shaping them. SSR data was analyzed by GENSURVEY (Vekemans & Lefebvre, 1997), FSTAT 2.9 (Goudet, 1995) and NTSYS-PC(Rohlf, 1993). Results affirm a genetic divergence between African and Latin American accessions. They also show a high genetic diversity and a low differentiation in the Ugandan accession. There is a substantial role played by the cassava mosaic disease (CMD) on cassava genetic constitution in respective districts.

Introduction:

Cassava (*Manihot esculenta*) is an allogamous and vegetatively propagated, neotropical crop that is also widely grown in tropical Africa and south east Asia. Sub Saharan Africa alone produces over 50% of the world's production, predominantly grown by small-scale farmers (Dixon et al, 1998). Cassava is grown mainly for its starchy roots and the leaves and forms a staple by an estimated 14 million people in Uganda (Bua, pers.comm, 2001). Cassava was introduced into Uganda after 1850 by Europeans and Arabs who were pushing into the interior from the coast of East Africa as a valuable safeguard against frequent hungry periods and famines which impeded trade and economic development along the trade routes (Langlands, 1970; Jones, 1959). Because of its excellent adaptability to erratic rainfall and low fertility soils, it became a major dietary staple, a famine reserve crop and a source of cash to many small-scale farming communities.

Cassava is probably thought to have originated in wild *Manihot esculenta* populations growing along the southern rim of the Amazon Basin in Brazil (Olsen & Schaal, 1999), many founder effects should have occurred, with the concomitant result of reduced diversity and increased genetic differentiation. For cassava, being mainly a vegetatively propagated crop, a further reduction in genetic diversity is likely over time due to

accumulation of systemic pathogens and the spread of a few, vigorous, well-adapted landraces. For instance the cassava mosaic disease (CMD) epidemic in Uganda in the late 80's and early 90's. In a survey carried out in 2000 in Mukono, Soroti and Apac districts in Uganda, the impact of the CMD epidemic on cassava diversity composition was clearly seen via the loss of previously well-known varieties.

However, the traditional farming system of slash and burn followed by 3-15 years of fallow practiced by farmers in Tanzania and the allogamous nature of cassava produces a large pool of volunteer seedlings that natural and human selection acts on to produce new varieties which maintains a high diversity (Fregene et al, 2003). In the mentioned survey in 2000, it was also observed that additional genetic variability had arisen from the use of volunteer seedlings by some farmers in Mukono district. In view of the outcrossing and highly heterogeneous nature of cassava differentiating phenotypic distinctiveness of varieties gets more complicated due to gene flow between varieties by hybridisation. Gene flow generates new polymorphism in the populations and increases effective population size thereby opposing random genetic drift, generating new gene combinations on which selection can potentially act (Balloux et al, 2002).

In Uganda identification and collection of cassava germplasm has predominantly relied on vegetative characteristics. The collections are maintained in the field in a continuous vegetative phase by cyclic pruning or periodic renewal of the entire collection every 2-4 years. In traditional farming systems, the concept of a variety can encompass very diverse genetic entities. Traditional naming and classification systems are often based on traits that are perceived subjectively in so doing it is not uncommon to find confusion between varieties or use of different names for the same cultivar (Elias et al.2001).

Determining the relationship between the basic units in a traditional classification system on the one hand and the genetic variability in the traditional farming systems in Uganda on the other hand is thus essential to conservation of genetic resources. Defining the genetic entities is crucial in breeding to identify and/or develop new cassava varieties to

be used as targets for efforts in producing high yielding varieties that meet the demands of farmers and consumers.

Using neutral genetic markers, gene genealogies can be used to assess relationships among alleles in populations. Insights into processes such as selection, fluctuation in population size, and population substructuring that affect the geographical and genealogical relationships among these alleles can be provided. In this study, using SSR markers, variation in allele frequency at many unlinked loci is the preferred way to assess genetic diversity and differentiation, and to estimate the strengths of various forces shaping them. In cassava, SSR markers have been used to search for duplicates in the CIAT core collection (Chavarriaga-Aguirre et al, 1999) and to analyze variation in natural populations of putative progenitors of cassava (Olsen and Schaal, 2001). A study of 67 unlinked loci, microsatellite loci from cassava landraces across three continents of Latin America, Asia and Africa have also been carried out to shed more light on the dynamics of genetic diversity and differentiation (Fregene et al, 2003). We assessed the genetic diversity and differentiation based on SSR markers of landraces from all over Uganda and a small subsection from Latin America and other African countries. The objectives of this study were to: assess the genetic diversity and differentiation of cultivars within and between different agro ecological zones in Uganda; also to determine how the Uganda cassava diversity compares with the total genetic diversity of species within Africa and the cassava collection maintained at CIAT. Genetic diversity is the key to progress in breeding and differentiation can serve as a tool to delineate heterotic pools. High levels of genetic differentiation, potentially representing heterotic pools, have been described for maize (Shull, 1952; Tomes, 1998) and robusta coffee (Leroy et al, 1993). Reliable estimates of population differentiation are crucial to understand the connectivity among populations and represent important tools to develop conservation strategies (Balloux et al, 2002) of cassava in Uganda.

Materials and methods

Plant materials:

The collection started in September through to December 2002 and covered 17 districts that lie between latitudes N02° 12¹ and S 00° 44¹, longitudes E029° 56¹ and E034° 21¹, and altitudes of 4451ft and 2177ft above sea level. Cassava is relatively recently introduced in Uganda. It is thought to have spread from Buganda to northwest (Bunyoro) around 1870, to the east in the early 19th century and to the north even later (Langlands, 1966). Cassava generally had an extremely limited distribution in Uganda in 1900 (Langlands, 1966). There are many biotic stresses cassava in Uganda has undergone since then the major of which is ACMVD in the late 1920s and later in the 1980s. Hence the forces affecting genetic differentiation in Uganda in the last century since its introduction can be assessed here.

Three of four or five counties in each district were selected at random and mature fields (5 months and above) were selected every 7-10 km along the roads that traversed each of the counties. In each farmer's field the different varieties were identified according to their morphological characteristics as well as by the name given by the farmer. Where no single variety dominated plants of the co-dominant varieties were sampled, labelled to be planted and maintained in NAARI. A total of 221 accessions were collected. A summary of the plant materials and their source can be viewed in appendix 1.

Studies have been done to assess the genetic diversity and differentiation of cassava landraces from primary and African centers of diversity using 67 marker loci (Fregene, 2003). Based on this work 22 Nigerian landraces from both the international collection at the International Institute of Tropical Agriculture (IITA) and improved genotypes from the Institute's cassava breeding programme or the 1950s breeding efforts at the Moor Plantation Experiment Station, Ibadan, Nigeria were included. One genotype 58308, has been used extensively as donor parent for resistance to CMD in the IITA program. In addition to this, 20 Tanzanian material was included from a previous study of diversity in Tanzania, 20 material from the Ghanaian germplasm bank, 20 material from Guatemala and 18 from holdings at CIAT and IITA. 9 groups or samples, based on country of origin,

were created to study genetic diversity and differentiation within each country and among countries. In all, 350 accessions were used with 272 coming from Ugandan farmers.

Simple Sequence Marker Analysis

DNA isolation was carried out from young leaf tissue harvested by CTAB method (Doyle & Doyle, 1987) at Med Biotech Laboratories, Kampala. A subset of 36 SSR markers with high polymorphism information content (PIC) was selected from 67 markers developed at CIAT (Fregene et al, 2003). In that study it was shown that the PIC does not increase appreciatively after 36 markers. The 36 markers were also chosen to represent a wide coverage of the genome. PCR was carried out using 10ng of DNA per reaction. The PCR product was denatured and electrophoresed on 6% polyacrylamide gels using Bio-Rad sequencing apparatus. Silver staining was done as described for these SSR markers (Mba et al, 2002). Allele sizes were then determined using computer software 'quantity One' (Bio-Rad Inc.) based upon an internal gel molecular marker size standard and exported to Microsoft Excel (Microsoft Inc) for further formatting as input files for statistical analysis. A strictly diallelic model of inheritance was adhered to hence markers with three or more alleles were eliminated. Parameters of genetic diversity and differentiation were then calculated from allele data using the computer packages GENSURVEY (Vekemans & Lefebvre, 1997), FSTAT 2.9 (Goudet, 1995) and NTSYS-PC (Rohlf, 1993).

Results

Data assessed on 250 accessions of cassava landraces using a total of 35 of 36 SSR loci, one eliminated for being monomorphic, was used to provide estimates for the genetic diversity and differentiation between country and within districts of Uganda.

Between countries, the landraces were grouped into 8 samples according to country of origin, Guatemala having two groups as observed in a previous diversity study (Fregene et al 2003). Within districts there were 18 groups represented. The number of alleles observed at each locus in the data set ranged from 2 to 12 alleles per locus (see fig.1) over the 35 loci. Genetic diversity parameters were calculated from SSR data within and

between country samples (table 1) and within districts in Uganda (table 2) samples. Standard deviations(SD) were estimated by jackknifing over loci (200 replications). The average gene diversity, H_e , that estimates the probability that two randomly selected alleles in a given accession are different was more than half and comparable for between Uganda districts and for between country at 0.5320 ± 0.0445 and 0.5649 ± 0.0698 respectively. On the whole the least values for average gene diversity were observed in Lira and Luweero districts while Kasese stands out with the highest value of 0.6208. This affirms earlier findings of higher varietal diversity in the western and southwestern districts of Uganda as opposed to those in the eastern districts (Otim-Nape et al, 2001). It is worth noting that these values are lowest for the districts that were worst hit by CMD. The average proportion of observed heterozygous individuals (H_o) between countries was 0.5423 ± 0.0285 while Uganda alone had 0.5530. This continues to affirm out crossing and highly heterogeneous nature of cassava. However, only 1% ($G_{st}=0.0192 \pm 0.0511$) of within district in Uganda was due to differentiation. On the other hand, 10% ($G_{st}=0.1078+0.0502$) of the overall heterozygosity ($H_t=0.6305 \pm 0.1696$) in all the country accessions could be attributed to differentiation among the samples from both Africa and Latin America.

Genetic differentiation averaged over all loci estimated by F_{st} (theta) was 0.103 ± 0.009 (jackknifing) and 0.082 ± 0.126 calculated by bootstrapping at 99% confidence interval (data not shown). This concurs with previous diversity studies in Tanzania hence confirming low differentiation between country samples as observed with G_{st} (Fregene et al, 2003). Pair wise calculations of F_{st} (theta) over all loci between pairs of country landraces and Uganda also showed there was lower differentiation between African countries compared with Latin American countries (Fregene et al, 2003), the lowest being with Ghana (0.039) and the highest being with Guatemala group one (0.2475). The dendrogram of landraces for UPGMA of pair wise F_{st} estimates had an outcome that also separates the African from Neotropical accessions with Guatemala separating in the two groups (Fig.2).

Genetic distance between all pairs of individual Uganda accessions was calculated by the 1- proportion of shared alleles (1-PSA) and presented graphically by a principle coordinate analysis (Fig. 3a). It showed that the Ugandan cassava is least related to the Neotropical. The PC1 and PC2 accounted for about 40% and 10% of the total variance respectively. The PCA for the Ugandan accessions (Fig.3b) showed clustering of the landraces in two groups with no observable difference between districts except Nakasongola. A similar substructure has been reported for earlier studies for Ghana, Tanzania and Nigeria. This feature in the African landrace collections is yet to be explained. The representation of cassava germplasm in the two groups from most of the other districts could probably be due to extensive movement of planting material which started with the mosaic epidemic as collective efforts were made in a bid to avert the shortage of planting material (Otim-Nape 2001, Otim-Nape,1997).

Discussion

The relatively high level of genetic diversity observed on the whole in this study is unexpected considering Uganda has reported two major cassava mosaic disease (CMD) epidemics before (Martin, 1928). The most recent CMD epidemic being in the last 10-15 years, since 1988, affected drastically the cassava varietal composition and saw a decrease in area planted to cassava at its peak between 1990-1994 (Otim-Nape et al, 2001). This finding continues to demonstrate the fact of active involvement of Ugandan farmers in continuous testing and the adaptation of new planting materials to their situations and their need to keep genetic variation. The results notably confirm the role of CMD as one of the major factors in selection force on the Uganda cassava genetic constitution with respect to districts of Uganda. It has been shown that the pattern of genetic divergence of an introduced species is usually non-random and strongly correlated to the environment (Clegg and Allard, 1972). It would be interesting to screen for the introgression of CMD resistance from the wild *Manihot glaziovii* in this cassava collection from earlier efforts in combating the disease in the 1920s and 30s (Jameson, 1964) and lately from Nigerian landraces (Fregene et al, 2003). It would also be

important to find out how much overall spontaneous recombination and farmer selection is going on in Uganda.

The other fundamental finding in this study is the continued clustering of Neotropical and African landraces according to region of origin as has been found in a previous cassava diversity study (Fregene et al, 2003). The African cassava accessions also appear to be structured in response to selection for adaptation to unique aspects of African agroecologies(Fresco, 1986; Nweke, 1994). The underlying factors behind the small differentiation between the Uganda (East Africa) and Ghana (West Africa) accessions however remains to be understood. Uganda being an inland country may have had its founding population from both the East and west coasts of Africa. More insight into this would be obtained from an assessment of cassava diversity in the Democratic Republic of Congo to the west or the Sudan to the north of Uganda.
