ESTABLISHMENT OF A PROGRAM IN BRAZIL FOR PRODUCING

DISEASE-FREE SEED OF BEANS (Phaseolus vulgaris)

ACKNOWLEDGMENTS

I want to express my gratitude to Drs. Sergio Fagundes, Bill Gregg, Flavio Popinigis, Clovis Wetzel, Clibas Vieira, Shiro Miyasaka, Alvaro S. Costa, Carlos Rava, and the rest of Brazilian colleagues for their valuable suggestions and open discussions on the subject. Their magnificent hospitality is gratefully acknowledged.

Report on the establishment of a program in Brazil for producing disease-free seed of beans (<u>Phaseolus vulgaris</u>)

Guillermo E. Galvez E.

Diseases of beans are more numerous in the tropics than in temperate zones, Wellman citing 280 diseases in the tropics as compared with 95 in the temperate zone. In the tropics their presence on this crop is not only affected by temperature, humidity, and association with other crops, but also their severity is connected with ecological conditions such as the altitude at which beans are grown. The high incidence of bean diseases is a major factor in the low average yield (600 kg/ha.) for the region in addition to other related factors. Most of the important bean diseases are seed-borne, thus transmitting the primary inoculum into new seasons and plantings.

Seed quality of beans in not only genetic, physical and physiological, but also phytosanitary; i.e., the presence of disease-causing bacteria, fungi, and viruses which affect seed germination, seedling emergence and vigor, and subsequent plant development. Latin American certification programs at present certify seed lots for varietal purity and germination only.

When disease-free seed produced at CIAT was planted on 80 small farms (1.1 ha/farmer) in Guatemala, yield increases of up to 300% were obtained; therefore, it may be possible to increase production up to 100% (without breeding new varieties) through the use of disease-free seed.

Siqueira and his co-workers in Rio Grande do Sul increased yields up to 1200 kg/ha. by the use of virus-free seed. The yield average in the region was 500 kg/ha. This success notwithstanding the use of certified

seed in Brazil is almost nil (0.2%) at the present time, according to the information gathered during visits to several institutions in Goiania, Vicosa, Campinas and Brasilia.

Disease-free seed production

The production of basic disease-free seed is easy to carry out, and does not require sophisticated equipment. It does need, however, trained personnel to be successful. The program is based on the fact that seed-borne pathogens of beans are not carried in 100% of the seeds. A general plan to clean disease-affected seeds of local Brazilian varieties could be as follows:

- To select at least 200 plants of each of the most commonly planted varieties from commercial fields, selecting for agronomic characteristics as well as for sanitary conditions.
- To plant 2 seeds/pot (15 20 cm. diam., 25 cm. depth), in sterilized soil. The pots are kept under greenhouse or very fine screenhouse conditions.
- 3. The plants have to be irrigated carefully, and an expert technician in bean diseases must observe them daily, hopefully twice a day. If any diseased plant is found, the whole pot is eliminated.
- 4. A program of intensive chemical control has to be implemented to ensure that seed cannot be reinfected from external sources.
- 5. At maturity, the remaining plants are harvested individually to avoid possible contamination of apparently healthy plants, found to be infected after laboratory tests. This is the Basic seed for Foundation seed production.

Foundation disease-free seed production

Foundation seed has to be produced in regions where climatic conditions are unfavorable for disease development or for high populations of vectors. A rainfall of 100 - 300 mm, a low relative humidity (40 - 60%), and temperature during the day of 25 - 35 C with full sunlight are ideal conditions for disease-free seed production in the field. Furrow irrigation facilities are needed.

Under these conditions, bacterial and fungal diseases, except root rots, are eliminated, and "clean" seed is produced. Common bean mosaic virus and its aphid vectors survive these conditions, therefore, careful inspection and excellent insect control is necessary to prevent infection.

Unfortunately the conditions mentioned are not easy to find in Latin America, making it necessary to prevent the presence of diseases by planting either in regions similar to those described above, or in seasons that approach these conditions. Brazil has the best ecological conditions in regions close to the San Francisco River Valley. However, its present infrastructure makes it impossible to think of this area as the only one to meet the bean seed requirements for the whole country. Furthermore, it would be necessary for the Government to declare this area restricted for seed production. The cost of disease-free seed produced there would be very high because of transportation costs.

There are three possibilities for the production of Foundation seed:

- Use new land at Experiment Stations of Embrapa or other agricultural institutions during the dry season.
- Use leased land in regions with low rainfall and low relative humidity
 in the large bean-producing states but distant from commercial bean
 production areas.

 Have an Embrapa Experiment Station in the San Francisco Valley devoted to seed production only.

Once the site is selected, the seeds must be planted 25-30 cm apart in furrows, in rows 1.00 m apart, it would be advisable to plant some rows of maize to separate varieties to avoid natural crossing, as well as to serve as relatively natural barriers for the dissemination of seed-borne pathogens. A minimum of four, preferably five, inspections of each field should be made during the crop season: 15, 30, 45 and 60 days after germination. The 15-day inspection is useful to detect common mosaic virus-infected plants; 30 days for bacterial blights, angular leaf-spot, webblight, etc.; 45 and 60 days for bacterial blights and anthracnose. Any plant showing an apparent symptom of any seed-borne disease must be rogued. A programmed chemical control of diseases and insect vectors is necessary. The ideal situation is not to have any plant infected with anthracnose, bacterial blights, wilts, common bean mosaic, etc.; however, under tropical environmental conditions this tolerance could be extended a little to 0.5 - 1%.

Only the pods not touching the soil should be harvested. Time of harvesting is critical; the mature pods should be picked as soon as possible.

Delayed harvesting can result in reduced germination in vitro and field emergence, as well as in increased seed infection by several organisms.

Before threshing, a windrow inspection is advisable. Seed must then pass a serology and greenhouse test for the presence of seed-borne diseases. This seed is the Foundation seed, the basis for the production of Certified seed. Certified seed should be planted in bean disease-free regions or under a program with considerable protection against the spread of diseases from adjacent commercial fields.

Special strategies for the small farmer

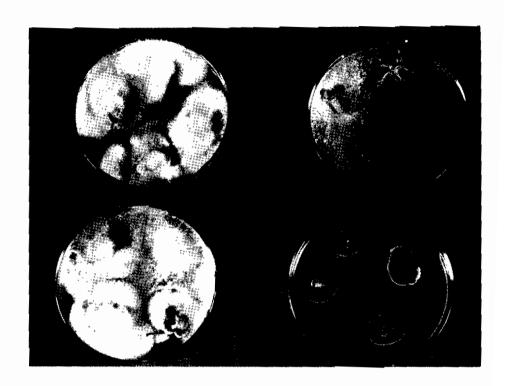

The final results of this program will not be seen unless the farmerthe final client-is taken into account. In Brazil the great majority of
commerical bean growers are small farmers who are poor, uneducated traditionalists. Therefore, it is difficult to convince them to buy certified
seed for the first time and even more so for each consecutive planting with
an autogamous plant. Special strategies are needed. Among them, ICTA
(Instituto de Ciencia y Tecnologia Agricolas) in Guatemala used to give the
"clean" seed, fertilizers and pesticides as part of the credit. This credit has to be on time for this short-term crop. ICTA then bought the seed
produced under their technical supervision giving the farmer a substantially
better price than they could obtain on the local market.

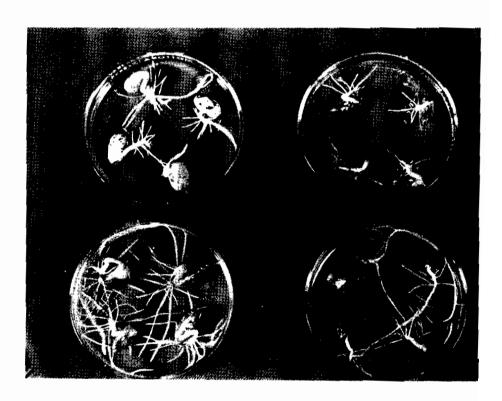

The small farmers could change technology if they are shown in <u>situ</u> the beneficial results. In Guatemala, for example, the neighbors wanted to buy clean seed from the seed producers, paying even higher prices than ICTA. And, of course, there is education, perhaps the key point of the whole process.

Certified seed production

The production of certified seed in large quantities could be stimulated through government tax exemptions, special prices and credit given in time to meet with crop needs. The seed growers do not want to deal with small farmers; they want to sell large amounts of seed; therefore, government agencies have to look for ways to buy seed and distribute it in small quantities. This is also true for fertilizers, pesticides, etc.

It is necessary to establish special regions within the country for seed production only. Any region where beans are produced for consumption or where experimental plots exist should be avoided.

Seeds obtained from a small farmer. They are 100% infected with seed-borne organisms.
Clean seed obtained at CIAT.
